Neural networks mad

Ophir Tanz, Cambron Carter

/ 5:00 am +08 • April 14, 2017

Ophir Tanz

Contributor

Ophir Tanz is the CEO of [GumGum](#), an artificial intelligence company that uses its expertise in computer vision. GumGum applies its capabilities to a variety of industries, from advertising to professional sports across the globe. Ophir previously worked at Carnegie Mellon University and currently lives in Los Angeles.

Cambron Carter

Contributor

Cambron Carter leads the image technology team at [GumGum](#), where he oversees the company's computer vision and machine learning solutions for a wide range of clients. He holds B.S. degrees in physics and electrical engineering from the University of Michigan and a M.S. in computer science from the University of Southern California.

If you've dug into any articles on artificial intelligence lately, you've probably come across the term "neural network." Modeled loosely on the way our own brains work, neural networks are a type of machine learning algorithm that can learn to recognize patterns in data without being explicitly programmed to do so.

networks enable computers to learn from being fec

The efficacy of this powerful branch of machine learning has been responsible for ushering in a new era of AI, a long-lived “[AI Winter](#).” Simply put, the neural network is one of the most fundamentally disruptive technologies in existence.

This guide to neural networks aims to give you a comprehensive understanding of deep learning. To this end, we’ll aim to explain the concepts behind neural networks without instead relying as much as possible on analogies and metaphors.

Thinking by brute force

One of the early schools of AI taught that if you load all the knowledge of the world into a powerful computer and give it as much data as possible, it will understand that data, it ought to be able to “think.” This was the approach taken by the team that built the chess-playing computers like IBM’s famous Deep Blue: By exhaustively calculating every possible chess move into a computer, as well as knowing every possible outcome, it could calculate every possible move and outcome into the future, and then calculate every subsequent moves to outplay its opponent. This

[masters learned in 1997.*](#)

With this sort of computing, the machine relies on a massive amount of pre-programmed logic: If this happens, do this; if that happens, do this — and so it isn’t human-style thought at all. It’s powerful supercomputing, for sure, but no

Teaching machines to learn

Over the past decade, scientists have resurrected the idea of teaching machines to learn. Instead of relying on a massive encyclopedic memory bank, but instead, they’re taught to find a way of analyzing input data that’s loosely modeled after the way our own brains work.

Machines — they’re just like us

An artificial (as opposed to human) neural network construct that enables machines to learn everything from playlist curation to music composition and image recognition. It consists of thousands of interconnected artificial neurons arranged sequentially in rows that are known as layers, forming a brain-like structure. In many cases, layers are only interconnected with the layers above them via inputs and outputs. (This is quite different from a biological brain, which are interconnected every which way.)

Source: GumGum

This layered ANN is one of the main ways to go about teaching computers to recognize objects. Feeding it vast amounts of labeled data enables it to learn to identify objects like (and sometimes better than) a human.

Just as when parents teach their children apples and oranges in real life, practice makes perfect.

Take, for example, image recognition, which relies on a type of neural network known as the convolutional neural network. This type of network uses a mathematical process known as convolution to identify objects in non-literal ways, such as identifying a partially obscured apple in a pile of fruit.

All aboard the network train!

So how do neural networks learn? Let's look at a very simple procedure called supervised learning. Here, we feed the network large amounts of training data, labeled by humans so that the network can essentially fact-check itself as it's learning.

Let's say this labeled data consists of pictures of apples and oranges. The pictures are the data; "apple" and "orange" are the labels. When a picture is fed into the network, the network breaks it down into its basic components, i.e. edges, textures and shapes. As these components pass through the network, these basic components are combined to form more complex concepts, i.e. curves and different colors which, when put together, look like a stem, an entire orange, or both green and orange together.

At the end of this process, the network attempts to predict what's in the picture. At first, these predictions will appear as random noise. This is because the learning has taken place yet. If the input image is an apple, the network's inner layers will need to be trained to recognize that.

The adjustments are carried out through a process of trial and error. The network tries to increase the likelihood of predicting "apple" for that input image, and continues to do so until the predictions start to improve. Just as when you're learning to identify apples and oranges in real life, for computers too, it's a process of trial and error. If you head, you just thought "hey, that sounds like learning to me".

So many layers...

Typically, a convolutional neural network has four hidden layers besides the input and output layers:

- Convolution
- Activation

In the initial convolution layer or layers, thousands of filters, scouring every part and pixel in the image, look for specific features.

more images are processed, each neuron gradually identifies features, which improves accuracy.

In the case of apples, one filter might be focused on leaves, another might be looking for rounded edges and yet others for thin, stick-like stems. If you've ever had to clean out your garage or prepare for a garage sale or a big move — or work — then you know what it is to go through everything, sorting items into themed piles (books, toys, electronics, objets d'art, etc.). A convolutional layer does with an image by breaking it down into these different components.

One advantage of neural networks is that they are capable of learning in a non-supervised way

What's particularly powerful — and one of the main reasons why neural networks have become so popular — is that unlike earlier AI methods (Deep Blue and Watson), they learn and refine themselves purely based on experience.

The convolution layer essentially creates maps — called feature maps — of the picture, each dedicated to a different filtered set of features. In this case, some neurons see an instance (however partial) of the central subject, while others see various other elements of, in this case, an apple. Because the convolution layer is fairly liberal in its identifying of features, it needs to make sure nothing of value is missed as a picture moves across the field of view.

Activation

One advantage of neural networks is that they are able to learn in a non-supervised way, which, in mathless terms, means that they can identify images that aren't quite as obvious — pictures of a person under direct sunlight and others in the shade, or piles of fruit on a counter. This is all thanks to the activation layer, which highlights the valuable stuff — both the straightforward

and the more subtle — and therefore more interesting — features, respectively, and sends them off to the appropriate category piles for further consideration.

Pooling

All this “convolving” across an entire image generally can quickly become a computational nightmare. Enter shrinks it all into a more general and digestible form. About this, but one of the most popular is “max pooling,” which feature map into a *Reader’s Digest* version of itself. In other words, if redness, stem-ness or curviness are featured.

In the garage spring cleaning example, if we were to follow consultant Marie Kondo’s principles, our pack rat would keep things that “spark joy” from the smaller assortment pile, and sell or toss everything else. So now we start by type of item, but only consisting of the items we keep. Everything else gets sold. (And this, by the way, even helps describe the filtering and downsizing that goes on.)

At this point, a neural network designer can stack several configurations of this sort — convolution, activation and pooling — down images to get higher-level information. In the first few layers, the images get filtered down over and over until barely discernable parts of an edge, a blip of red or a blob of blue. Subsequent, more filtered layers will show entire apples and oranges. To start getting results, the fully connected layer compares

“pooled,” feature map is “fully connected” to output the items the neural network is learning to identify.

learning how to spot cats, dogs, guinea pigs and goats. In the case of the neural network we've been using, there are two output nodes: one for "apples" and one for "orange".

If the picture that has been fed through the network has already undergone some training and is getting it's likely that a good chunk of the feature maps contain features. This is where these final output nodes start reverse election of sorts.

Tweaks and adjustments are required for a neuron better identify the data

The job (which they've learned "on the job") of both essentially to "vote" for the feature maps that contain more the "apple" node thinks a particular feature map more votes it sends to that feature map. Both nodes feature map, regardless of what it contains. So in this case send many votes to any of the feature maps, because "orange" features. In the end, the node that has seen, for example, the "apple" node — can be considered the not quite that simple.

Because the same network is looking for two different things — the final output of the network is expressed as probabilities assuming that the network is already a bit down the road. The predictions here might be, say, 75 percent "apple" and 25 percent "orange". If it's earlier in the training, it might be more inaccurate, like 60 percent "apple" and 80 percent "orange." Oops.

If at first you don't succeed, t

So, in its early stages, the neural network spits out form of percentages. The 20 percent “apple” and 8 clearly wrong, but since this is supervised learning network is able to figure out where and how that er checks and balances known as backpropagation.

Now, this is a mathless explanation, so suffice it to feedback to the previous layer’s nodes about just h That layer then sends the feedback to the previous game of telephone until it’s back at convolution. Tw to help each neuron better identify the data as ever go through the network.

This process is repeated over and over until the ne and oranges in images with increasing accuracy, e percent correct predictions — though many engine acceptable. And when that happens, the neural ne can start identifying apples in pictures professional
